(Received 15 March 2018; revised manuscript received 26 May 2018; published 19 July 2018)

Recent experiments in graphene heterostructures have observed Chern insulators—integer and fractional quantum Hall states made possible by a periodic substrate potential. Here, we study theoretically that the competition between different Chern insulators, which can be tuned by the amplitude of the periodic potential, leads to a new family of quantum critical points described by QED$_3$-Chern-Simons theory. At these critical points, $N_f$ flavors of Dirac fermions interact through an emergent U(1) gauge theory at Chern-Simons level $K$, and remarkably, the entire family (with any $N_f$ or $K$) can be realized at special values of the external magnetic field. Transitions between particle-hole conjugate Jain states realize "pure" QED$_3$, in which multiple flavors of Dirac fermions interact with a Maxwell U(1) gauge field. The multiflavor nature of the critical point leads to an emergent SU($N_f$) symmetry. Specifically, at the transition from a $\nu = 1/3$ to 2/3 quantum Hall state, the emergent SU(3) symmetry predicts an octet of charge density waves with enhanced susceptibilities, which is verified by DMRG numerical simulations on microscopic models applicable to graphene heterostructures. We propose experiments on Chern insulators that could resolve open questions in the study of (2 + 1)-dimensional conformal field theories and test recent duality inspired conjectures.

DOI: 10.1103/PhysRevX.8.031015

I. INTRODUCTION

Perhaps the most remarkable example of emergence in condensed matter physics is the appearance of deconfined gauge fields, which by now is well established in the context of the fractional quantum Hall effect, whose low-energy physics is captured by a Chern-Simons gauge theory. Here, we discuss a family of quantum phase transitions between different quantum Hall states that, owing to the emergent gauge fields, are strikingly different from conventional phase transitions.

At the same time, recent experimental advances have brought their physical realization within reach. There has been rapid progress in achieving quantum Hall physics [1–3] in the presence of a periodic potential at the scale of the magnetic length. Moiré patterns between boron-nitride and bilayer graphene [4–6], as well as patterned gate electrodes [7], have been utilized to create a superlattice potential, leading to the realization of integer Chern insulator (ICI) phases [8,9] within the Hofstadter butterfly [10]. While these phenomena are present even in models of noninteracting electrons, recent experiments on bilayer graphene have demonstrated the existence of fractional Chern insulators (FCIs) [11], fractional quantum Hall states that can only occur through the interplay between the periodic potential and electron-electron interactions. While there is significant theoretical literature on FCI states [12–16] (also see reviews [17,18]), recent experimental progress calls for a study of the quantum phase transitions between the rich variety of phases that can be tuned by the potential, which have attracted less attention [19].

Phase transitions between distinct quantized Hall states have been studied since the early days of the quantum Hall effect, typically in the presence of disorder, which leads to plateaus of quantized Hall conductance on changing the magnetic field or electron density [20–24]. Instead of traditional plateau transitions, we will discuss transitions that may be tuned by the amplitude of the periodic potential at fixed magnetic field and density, which cannot be realized in the disorder dominated regime [19] and have not been previously discussed. In particular, we will focus on a class of quantum phase transitions that can be...
approached using the composite fermion description [25–27], where a new set of fermions is obtained from electrons (or bosons) by a flux attachment procedure. Microscopically, the periodic potential alters the dynamics of the composite fermions, inducing a change in their band topology. At the critical point, the composite fermions form multiple Dirac cones. This leads to a class of critical theories in $2 + 1D$ that take the form of quantum electrodynamics (QED), with multiple flavors ($N_f$) of Dirac fermions coupled to a $U(1)$ gauge field arising from flux attachment. An additional Chern-Simons term may also be present. Previous discussions of the plateau transition [20–23] have typically considered the Chern number of the composite fermions changing by unity ($N_f = 1$), in both lattice and disordered systems. This is the only natural scenario for the disordered case and is a special case of the more general theory discussed below, where lattice translations endow the system with larger symmetry, leading to several new features, in particular, an enlarged SU($N_f$) flavor symmetry that will have important consequences. There have also been some studies on the FCI transition with $N_f = 2$ [28–31], although these apply to FCI transitions of lattice bosons rather than electronic systems.

The family of critical theories we find are dubbed QED$_3$-Chern-Simons theory, each of which is labeled by two numbers: the number of Dirac fermion flavors $N_f$ and the Chern-Simons level $K$. It is believed that most (if not all) of these critical theories will flow into $(2 + 1)$-dimensional conformal field theories (CFTs) in the infrared. However, the properties of those theories are rather poorly understood. Indeed, there has been a large effort to study the IR properties of pure ($K = 0$) QED$_3$ [32–45], but calculating properties at small $N_f$ remains an open issue. Several of these theories have applications to other long-standing problems in condensed matter physics, for example, the theory with $N_f = 4$, $K = 0$ has appeared in theories of high temperature superconductivity in the cuprates [46] and spin liquid physics in frustrated magnets [38,47–50]. They also have interesting duality properties [51–55], and in light of the duality proposal, the self-dual $N_f = 2$, $K = 0$ theory [55–59] has a surprising connection to the “deconfined” critical points that were first discussed in the context of quantum magnets [60–62].

More generally, understanding the properties of interacting CFTs is a central quest in various fields of physics. In $2 + 1$ dimensions, there are a few CFTs that are well understood and can be realized experimentally, such as the Wilson-Fisher theories related to spontaneous symmetry breaking [63]. The FCI transitions discussed here could significantly expand the list, as the whole family of QED$_3$-Chern-Simons theory may be realizable within the experimental scenario we discuss. For example, we show pure QED$_3$ with arbitrary $N_f$ can be realized at the transitions between the particle-hole conjugate partners of the Jain sequence states. From an experimental point of view, the FCI transitions can be accessed by tuning the strength of the periodic potential, which has already been demonstrated experimentally [7,64]. Various critical exponents may also be measurable from the charge density wave susceptibility and tunneling conductance. We therefore believe that future experimental study may provide new insights on the long-standing and interdisciplinary problems regarding interacting CFTs in $2 + 1$ dimensions.

The rest of the paper is organized as follows. In Sec. II, we review free-fermion phase transitions between integer Chern insulators, where multiple Dirac cones can appear at special values of the magnetic field and electron density, where they are protected by magnetic translation symmetry [65]. The free-fermion physics is an important building block of our analysis, since a fractional Chern insulator can be understood as an integer Chern insulator of composite fermions [66,67]. In Sec. III, we consider a concrete example of a phase transition between two neighboring FCI phases with $\sigma_{xy} = 1/3$ and $\sigma_{xy} = 2/3$. We show that the transition can be realized in an experimentally feasible model, provide numerical confirmation using infinite density matrix renormalization group (iDMRG) simulations, and use the composite fermion approach to demonstrate how pure QED$_3$ arises at the critical point.

In Sec. IV, we discuss the general composite fermion construction of FCI transitions: Intuitively, they arise as Chern-number changing transitions of composite fermions. Therefore, like the free-fermion case, the magnetic translation symmetry of composite fermions can give rise to multiple Dirac cones, but with the added physics of an emergent dynamical $U(1)$ gauge field. We show how the whole family of QED$_3$-Chern-Simons theory can emerge at such critical points, and in particular, pure QED$_3$ theories can be realized at transitions between particle-hole conjugate partners of the Jain sequence. In Sec. V, we elaborate on the physical properties of QED$_3$-Chern-Simons theories. For example, a critical theory with $N_f$ Dirac fermions will have an emergent SU($N_f$) flavor symmetry. The emergent flavor symmetry will yield the degeneracy of the charge-density wave order parameter at $N_f^2 - 1$ distinct crystal momenta. The corresponding scaling dimensions are calculated analytically within a large-$N_f$ expansion. Using iDMRG simulations, we indeed find evidence for the emergence of SU(3) symmetry at the critical point between $\sigma_{xy} = 1/3$ and $\sigma_{xy} = 2/3$ phases, implying the emergence of pure $N_f = 3$ QED$_3$. We also discuss the properties of monopole operators, which in this context are nothing but the electron creation/destruction operators and their experimental consequences for probes sensitive to the electronic Green’s function. In Sec. VI, we point out that the transition of the bosonic $\nu = 1/2$ Laughlin state into a Mott insulator is strongly constrained by the level-rank duality results of Hsin and Seiberg and Beninin et al. [68,69], and we discuss their physical consequences. In Sec. VII, we further discuss the experimental setup for the FCI transitions, including a
more experimentally straightforward transition between a \( \sigma_{xy} = 1/3 \) FQH state and a \( \sigma_{xy} = 1 \) Chern insulator. In Sec. VIII, we summarize and discuss future interesting directions. The appendix is devoted to the details of large-\( N \) calculation and generalizations of microscopic models for the phase transitions.

II. FREE FERMIONS: A WARM-UP

We begin by reviewing transitions between integer Chern insulators at fixed density and flux, since these form the building block of our later fractionalized analysis. Throughout, we use units in which the unit cell of the lattice is \( a^2 = 1 \) and \( (e^2/h) = 1 \), so that the fundamental flux quantum is \( \phi_0 = 2\pi \) and the fundamental conductance is \( (e^2/h) = (1/2\pi) \). While we quote the value of \( \sigma_{xy} \), we will express it in units of \( e^2/h \) so that the \( 2\pi \) factor drops out. The magnetic field is measured in terms of the density of flux quanta per unit cell, \( \phi = (a^2 B/\phi_0) \). Chern insulators are best understood through the relation between the electron density per unit cell \( n \) and the flux density \( \phi \): Any gapped phase of matter must obey the Diophantine condition [70,71]

\[
\mathcal{L}_{\text{eff}}[A] = \frac{C}{4\pi} AdA + sA_0, \tag{2}
\]

where \( C, s \) are invariants which characterize the phase. From the Streda formula [70], the Hall conductance is \( \sigma_{xy} = (dn/dB) = C/2\pi \), while \( s \) can be thought of as the density of electrons “glued” to each lattice cell [71]. For any free-fermion state, \( C, s \in \mathbb{Z} \), while they may be rational fractions in a FCI. Galilean invariance requires \( s = 0 \), so nonzero \( s \) indicates strong lattice effects—these are the Chern insulators.

Experimentally, \( C \) and \( s \) can be determined by measuring electrical properties such as the resistance or compressibility in the plane of \( n \) and \( \phi \) (a “\text{Wannier plot}”). Gapped FCI and ICI phases appear as lines of incompressibility in this plane, from which the invariant can be read off as a slope and intercept (though, of course, the phases will only extend over a finite range of \( \phi \)) [4–6,11]. Importantly, two such lines may cross at some point \( \phi_*, n_* \) indicating competition between two different ICIs or FCIs. In Fig. 1, we illustrate how this competition may evolve as a tuning parameter, such as the lattice potential changes. The gap at \( \phi_*, n_* \) closes and reopens as it transfers between the two different trajectories, indicating a Chern-number changing transition.

The Diophantine condition places a constraint on the Chern-number changing transitions that can occur at fixed density and flux. If \( C \) and \( s \) change by \( \Delta C, \Delta s \) across the transition, we must have \( 0 = \Delta C \phi_* + \Delta s \). Letting \( \phi_* = (p/q) \), this implies \( p \Delta C = -q \Delta s \). Since \( p, q \) are coprime, we conclude that \( \Delta C \) is an integer multiple of \( q \). Thus, while naively one might suppose only \( |\Delta C| = 1 \)

 transitions are generic, fractional flux stabilizes higher Chern-number changing transitions [70–72].

In the free-fermion limit, \( C \)-changing transitions arise from gap closings in the underlying band theory. The total Chern number of an integer phase is determined by summing up the Chern numbers of occupied bands. As a parameter such as the lattice potential amplitude changes, the conductance and valence bands may touch, closing the gap and transferring the Chern number between them. The transfer of Chern number \( \Delta C \) between the two is mediated by the formation of \( \Delta C \) Dirac points, as illustrated in Fig. 2. We review the field-theoretic description of the resulting transition to illustrate the role of the invariant \( s \).

The electromagnetic response theory for a \( C, s \)-insulator is

\[
\Delta C = \frac{C}{4\pi} AdA + sA_0, \tag{8}
\]

where \( A \) is the external electromagnetic gauge field, as verified by \( (\delta \mathcal{L}/\delta A_0) = n = C(B/2\pi) + s \). Here (and later), \( AdA \) is a shorthand notation for the Chern-Simons

![changing the superlattice potential strength](image)

**FIG. 1.** Red and blue lines represent gapped trajectories labeled by \( (C, s) \) and \( (C', s') \), respectively, which intersect at \( (n_*, \phi_*) \). For a generic value of the tuning parameter \( m \) (superlattice potential strength), one type of gap will “win” over the other at the crossing. At the critical value \( m = m_c \), the gap closes and their relative strength is exchanged; this is the manifestation of a Chern-number changing transition.

**FIG. 2.** Landau levels in the presence of a superlattice potential. Each Landau level splits into two subbands, so that, at \( n = 2/3 \), the two lowest subbands are filled. (a) Chern number and gap versus potential strength \( U_0 \) at \( n = 2/3 \). (b) The band structure at the transition \( (U_0 \approx 0.79) \) shows three emergent Dirac cones which mediate the transition between the \( C = 1 \) and \( C = -2 \) insulators.
term $A \wedge dA$. For a transition between invariants $(C_2, s_2)$ and $(C_1, s_1)$ at rational flux $\phi_\nu$, we define a vector potential $A_\nu = (0, A_\nu)$ such that $\nabla \times A_\nu = 2\pi \phi_\nu$ produces the uniform magnetic field associated to $\phi_\nu$, and let $\Delta C = C_2 - C_1$, $\bar{C} = (C_2 + C_1)/2$. The proposed Lagrangian is

$$\mathcal{L} = \sum_{l=1}^{\Delta C} \bar{\psi}_l (i\partial_t + \bar{A} - \bar{A}_s - m) \psi_l + \frac{\bar{C}}{4\pi} (A - A_s) d(A - A_s) + n_s A_0.$$  

(3)

Subtracting $A_\nu$ ensures that, even though the Dirac fermions couple to $A_\nu$, they see no net field at $\phi_\nu$. The mass $m$ is a phenomenological parameter that tunes the Dirac fermions to be in a gapless phase. This is seen explicitly in $k$-space [65]. Defining a Chern-Simons response proportional to $\frac{1}{2} \left( \frac{m}{|m|} \right)$.

Integrating out the fermions, we obtain

$$\mathcal{L} = \left( \bar{C} + \frac{1}{2} \frac{\Delta C}{m} \frac{m}{|m|} \right) (A - A_s) d(A - A_s) / 4\pi + n_s A_0$$  

(4)

$$= \left( \bar{C} + \frac{1}{2} \frac{m}{|m|} \Delta C \right) A dA / 4\pi + (\bar{s} + \frac{m}{|m|} \Delta s) A_0,$$  

(5)

where we have used the Diophantine relations $\Delta C \phi_\nu = -\Delta s$ and $n_s = \bar{C} \phi_\nu + \bar{s}$. This ensures that we produce the desired response of Eq. (2) on either side of the transition.

This leaves open why the mass of the Dirac fermions are identical; in the absence of a symmetry relating them, the transition would instead occur through a sequence of $\Delta C = 1$ transitions. The desired symmetry is of course the magnetic algebra. Letting $T_x, T_y$ denote translations by the Bravais vectors of the lattice,

$$T_x T_y = e^{2\pi i \phi} T_y T_x.$$  

(6)

Since the magnetic algebra acts projectively on the fermions, at flux $\phi = (p/q)$, this requires $q$-fold degeneracies, guaranteeing that the Dirac points come in groups of $\Delta C = q$. This can be seen explicitly in $k$-space [65]. Defining a magnetic Brillouin zone with respect to the commuting translations $T_x, T_y$, the symmetries act on eigenstates $|k_x, k_y, j\rangle$ according to $T_x |k_x, k_y, j\rangle = e^{ik_x} |k_x, k_y, j\rangle$ (j is a band index) and $T_y |k_x, k_y, j\rangle = e^{ik_y} |k_x + 2\pi p/q, k_y, j\rangle$. The latter relation cyclically permutes $q$ points in the magnetic Brillouin zone. Therefore, if the system has a Dirac cone (denoted by $\psi_1$) at $(k_x, k_y)$, another $q - 1$ copies will automatically appear at $(k_x + 2\pi p/q, k_y)$. Under the translational operation, the resulting $q$-flavors of the Dirac fermion transform as

$$T_y \psi_1 = e^{ik_y} \psi_1,$$  

$$T_x \psi_1 = e^{ik_x + 2\pi i (p/q)} \psi_1.$$  

(7)

This forms a subgroup of SU($q$) under which only the singlet mass term $m \sum \bar{\psi} \psi$ is symmetric, which is the tuning parameter for the phase transition. Other mass terms, i.e., $\bar{\psi}_l M_{lj} \psi_j$ ($M \neq 1$), will break the magnetic translation symmetry.

As the magnetic flux deviates away from $\phi_\nu$, the residual field is seen by the Dirac fermions. Together, they will form $\Delta C$-fold degenerate Landau levels, opening up Hall gaps at total Chern number $C = C + (i + \frac{1}{2}) \Delta C, i \in \mathbb{Z}$. These are precisely the trajectories allowed by the Diophantine condition $n = n C \phi + s$ near $\phi_\nu$, and correspond to the formation of Chern $\Delta C$-bands. This makes precise the sense in which a Chern $C$-band is like “$C$-copies” of a Landau level; these copies are just the valley index of the $C$-Dirac fermions, which are permuted under the magnetic algebra as a subgroup of SU($C$).

A. Model realization

Chern-number changing transitions can be realized in any model without Galilean invariance, such as tight-binding models or continuum Landau levels with an additional weak lattice potential. While the former have been the subject of most numerical studies, the latter are most relevant to recent experiments in graphene heterostructures (see Sec. VII), so they will be our focus. In this paradigm, a strong magnetic field applied to a two dimensional electronic gas (2DEG) first gives rise to flat Landau levels with a magnetic length $\ell_B$ much larger than the atomic scale, split by a cyclotron energy $\hbar \omega_c$. An additional “superlattice” is then applied (via lithography or a moire pattern) at a length scale comparable to $\ell_B$ but with an amplitude small compared to $\hbar \omega_c$. In this limit, it is justified to project the superlattice into the Landau level (s) closest to the Fermi level. Landau level projection kills off wave vectors that are large compared to $\ell_B^{-1}$, so we consider superlattices of the general form

$$\mu(r) = U_0 \int dr \sum_{m} V_m e^{i r G_m} n_s + \text{H.c.},$$  

(8)

where $G_m$ are the smallest several reciprocal vectors of the superlattice. Here we consider a square lattice potential with $G_1 = (2\pi/a)(1, 0), G_2 = (2\pi/a)(0, 1), G_3 = (2\pi/a)(1, 1), G_4 = (2\pi/a)(1, -1), and V_1 = V_2, V_3 = V_4$, where $a$ is a lattice constant.

In the presence of a finite potential, the flat Landau levels broaden and split (and neighboring Landau levels may mix once the potential strength $U_0$ is comparable to the Landau level splitting). Solving for the band structure via standard methods [65,73,74], we see that Chern-number changing transitions can be induced simply by tuning the potential strength $U_0$ or the lattice shape $V_m$. At flux $\phi = p/q$ per unit cell of the superlattice, a Landau level splits into $p$ subbands, each with a $q$-fold degeneracy. As the $U_0$, $V_m$ change, the subbands can touch at $q$-fold Dirac points.
III. TRANSITION BETWEEN THE $\sigma_{xy}=1/3$ FQH EFFECT AND A $\sigma_{xy}=2/3$ FCI

In the presence of strong interactions, gaps can arise at fractional $C$ and $s$; these are the fractional quantum Hall effects ($C \neq 0$, $s = 0$) and fractional Chern insulators ($C \neq 0$, $s \neq 0$). Transitions between them are the main focus of the rest of the paper.

A. Model

We begin with a concrete example: the transition between a continuum $C = 1/3$ Laughlin state and a $C = 2/3$ FCI. As before, we consider a flat continuum Landau level with the addition of a square superlattice potential described in Fig. 3, but with the addition of a Coulomb interaction. The transition will be driven by the competition between the lattice amplitude $U_0$ and the Coulomb scale $E_C$. We consider flux density $\phi = 2$ and electron density $n = 2/3$, giving filling fraction $\nu = 1/3$. At $U_0 = 0$, the electrons fill $1/3$ of the LLL, where interactions stabilize the $\nu = 1/3$ Laughlin state ($C = 1/3$, $s = 0$). When $U_0 > 0$, the LLL splits into two subbands, and when $U_0$ is sufficiently strong, the lower band, which carries $C = 1$, will be $2/3$ filled, while the upper band, with $C = 0$, will be empty. For appropriate choices of $V_m$, the subbands are very flat (Fig. 3), i.e., the bandwidth $W$ of the subbands is small compared with the gap $\Delta$ between the subbands. Following the philosophy of earlier lattice FCI studies (e.g., Refs. [13–16]), we expect an $\sigma_{xy} = 2/3$ FCI may appear ($C = 2/3$, $s = -2/3$) for an appropriate ratio of $U_0/E_C$. Consequently, $U_0/E_C$ may drive a direct phase transition between a $\sigma_{xy} = 1/3$ FQH state and the $\sigma_{xy} = 2/3$ FCI.

B. iDMRG numerical simulations

The existence of continuous transition needs further substantiation since there might very well be a first order transition or an intermediate phase. To this end, we use the iDMRG method [75,76] developed for quantum Hall problems in Refs. [77,78]. We wrap the 2D system onto a cylinder that is infinite along the $x$-direction but compact along the $y$-direction, with circumference $L_y$. The Coulomb interaction is taken to have the $k$-space form $V(k) = E_C(2\pi/k)\tanh(kd)$, where we take into account metallic gates (at a distance $d$) are screening the Coulomb interaction, as are present in recent experiments [11]. Here, we fix $d = 2a$, twice the lattice spacing. At $\phi = 2$, $a = \sqrt{4\pi\ell_B}$, so we consider a cylinder of circumference $L_y = 9a \approx 31.9\ell_B$. The Coulomb interaction strength $E_C$ is fixed to $E_C = 1$, while superlattice amplitude $U_0$ is increased from zero in increments of $\Delta U = 0.001$. The Hall conductivity is computed by measuring the change of polarization charge during adiabatic flux insertion [79].

In Fig. 4, we observe a very sharp phase transition between $\sigma_{xy} = 1/3$ and $\sigma_{xy} = 2/3$ phases driven by $U_0$. The correlation length peaks at the transition and grows with the DMRG bond dimension “$\chi$.” While finite-circumference and DMRG accuracy effects make it difficult to conclusively identify whether the phase transition is continuous or first order, several observations are in favor of a continuous transition. First, there is no discontinuity in the derivative of energy $\partial E/\partial U_0$ across the phase transition. Second, unlike the first order metal-FCI transition in Ref. [80], the correlation length [81] appears to diverge on both sides of the transition, and at the transition it increases with the DMRG bond dimension $\chi$, as would be expected from the theory of “finite entanglement scaling” [82].

Though we have studied the square lattice potential most extensively due to its numerical advantages, we note that we observe an analogous transition for a triangular lattice potential, again at $\phi = 2$, $n = 2/3$. Therefore, this type of transition may be observable in the boron-nitride/graphene heterostructures realized in Ref. [11].

To further understand the nature of the phase transition, we will first analyze the possible critical theory using the composite fermion construction, which predicts an emergent SU(3) symmetry. In Sec. V, we provide numerical evidence for this emergent SU(3) symmetry, which can only arise if the transition is continuous.
Thus, the \( \nu = 1/3 \) FQH state arises when the CFs form a \( C = \sigma_{xy}^{\text{CF}} = 1 \) integer QH state, while the \( \sigma_{xy} = 2/3 \) state arises when the CFs have Chern number \( C = -2 \). So from the perspective of CFs, the transition is a \( C = 1 \) to \( C = -2 \) Chern-number changing transition. This transition arises for the same reason the lattice potential drives such transitions for electrons: The CFs also experience a lattice potential, 

\[
\mu_{\text{CF}} = U_{\text{CF}} \int \sum_{m=1}^{4} (V_n^m e^{i r \mathbf{s}_n + \text{H.c.}}),
\]

where the amplitude \( U_{\text{CF}} \propto U_0 \) and the amplitudes \( V_n^m \) are some effective renormalized constants. Because of flux attachment, the average flux seen by the composite fermions is \( \phi_{\text{CF}} = \phi - 2n = 2/3 \) per unit cell; e.g., they are at filling 1. Without the potential, the composite fermions fill their LLL (with \( C = 1 \)), generating the \( \sigma_{xy} = 1/3 \) FQH state. But once the potential strength \( U_{\text{CF}} \) is comparable to the composite fermion cyclotron gap \( \omega_{\text{CF}} \), the CF bands can touch and the Chern number may change to \(-2\), giving the \( \sigma_{xy} = 2/3 \) FCI state, similar to the free-fermion example discussed in Fig. 2. Such a \( \Delta C = 3 \) transition relies on the fact that the CFs see flux \( \phi_{\text{CF}} = 2/3 \), even while the electron flux is \( \phi = 2 \).

At the transition point, the composite fermions will form three Dirac cones, which are protected by the magnetic translation symmetry (since \( \phi_{\text{CF}} = 2/3 \)). The critical theory is

\[
\mathcal{L} = \sum_{I=1}^{3} \bar{\psi}_I (i \partial^\mu + a_{\mu}^I) \psi_I - \frac{1}{8\pi} a_{\mu} a_{\nu} (a_{\mu} - A_{\mu}) d (a_{\nu} - A_{\nu})
\]

Here, \( \psi_I \) are the two-component Dirac fermions interacting with a dynamical \( U(1) \) gauge field \( a_{\mu} \) that arises from flux attachment. A Maxwell-like term for the gauge field \( a_{\mu} \) is also present, which we suppress in the formal Lagrangian for notational convenience. \( A_{\mu} \) is the probe (external) gauge field, which couples to the charge of the electrons. For notational simplicity, we implicitly measure \( A_{\mu} \) and the electron density relative to their values at the transition \( A_{\mu}^I, n_{\nu} \); this could be made explicit as in Eq. (3), to account for the change in \( \sigma_{xy} \), but these terms have no influence on the dynamics. The first two terms are very similar to the free-fermion case in Eq. (3) (with \( \tilde{C} = -\frac{1}{2} \)), the only difference being that the Dirac fermions are interacting with the dynamical \( U(1) \) gauge field instead of a static background field. Meanwhile, the third Chern-Simons term encodes the flux attachment constraint.

The transition theory is a pure QED\(_3\) with three flavors of Dirac fermions, and the tuning transition parameter is the mass term of composite fermions, \( m \sum_{I=1}^{3} i \bar{\psi}_I \gamma_\mu \psi_I \). Once the composite fermions are gapped, integrating them out gives an effective theory depending on the sign of \( m \):

\[
\mathcal{L}' = \frac{m}{|m|} \frac{3}{8\pi} \frac{a_{\mu} a_{\nu} - A_{\mu} A_{\nu}}{\pi} d A_{\mu} - \frac{1}{8\pi} A_{\mu} d A_{\mu}. \quad (11)
\]

After integrating out \( a_{\mu} \), we obtain \( \mathcal{L}_{\text{eff}} = \{3 - \text{sign}(m)\}/6\} (1/4\pi) A d A \). Therefore, the theory describes the \( \sigma_{xy} = 1/3 \) phase for \( m > 0 \) and the \( \sigma_{xy} = 2/3 \) phase for \( m < 0 \).

Before closing this section, we mention a technical aside. Strictly speaking, we should write Eq. (10) a little differently for it to be free of the parity anomaly. First note, the flux attachment procedure can be alternatively formulated using a parton construction, writing the electron as \( c = \psi_{\nu} \); here, \( b \) is a gauge charged (and electrically charged) boson. Putting the boson \( b \) in the \( \nu = 1/2 \) Laughlin state is
equivalent to attaching two flux quanta to the electron $c$, and the fermionic parton $\psi$ is then nothing but the composite fermion. If we represent the three-current of $b$ as $d \wedge \beta/2\pi$, then we obtain

$$\mathcal{L} = \mathcal{L}_{\text{CF}}[a, \psi] + \frac{1}{2\pi} (a - A) dB - \frac{2}{4\pi} \beta dB. \quad (12)$$

Now, we put the composite fermions $\psi$ into a Dirac band structure such as Fig. 2, and then we have

$$\mathcal{L}_{\text{CF}}[a, \psi] = \sum_{l=1}^{3} \bar{\psi}_l (i \partial + \sigma) \psi_l - \frac{1}{8\pi} ada. \quad (13)$$

The theory is now free of parity anomaly, and the Chern-Simons terms are properly quantized. Finally, “integrating out” $\beta$ will lead to Eq. (10). The last step requires some care, but those finer points do not affect the dynamics of the transition.

IV. A FAMILY OF QED$_3$-Chern-Simons THEORY WITH ARBITRARY DIRAC FLAVOR

A. Composite fermion construction for the transition

The analysis above can be extended to a more general framework for phase transitions between FCI states. In general, the CF is obtained by attaching $k$ flux quanta to the electrons, with $k$ odd for bosons and $k$ even for fermions. After flux attachment, the CFs will see an effective flux density $\phi_{\text{CF}} = \phi - nk$ and still have particle density $n$. FCIs arise when the composite fermions form integer Chern insulators satisfying $n = C_{\text{CF}} \phi_{\text{CF}} + s_{\text{CF}}$ for $C_{\text{CF}}, s_{\text{CF}}$ integers [12,66]. From these relations, the fractional $C, s$ invariants of the electrons are related to those of the CFs by

$$\sigma_{xy} = C = \frac{C_{\text{CF}}}{kC_{\text{CF}} + 1}, \quad s = \frac{s_{\text{CF}}}{kC_{\text{CF}} + 1}. \quad (14)$$

The phase transition between two states in the same Jain sequence, with $\sigma_{xy} = C_1/(kC_1 + 1)$ and $\sigma_{xy} = C_2/(kC_2 + 1)$, is then understood as a CF Chern-number changing transition from $C_1$ to $C_2$. As we discussed before, the Chern-number changing transition will be accompanied by a gap closing, at which $|C_2 - C_1|$ Dirac cones emerge. The resulting effective theory for a transition is a straightforward generalization of Eq. (10):

$$\mathcal{L} = \sum_{l=1}^{3} \bar{\psi}_l (i \partial + \sigma - m) \psi_l + \frac{C_2 + C_1}{8\pi} ada$$

$$+ \frac{1}{4k\pi} (a - A) d(a - A). \quad (15)$$

In general, we have $N_f = |C_2 - C_1|$ Dirac fermions interacting with a Chern-Simons term at the level $K = (C_2 + C_1)/2 + 1/k$. The Chern-Simons term in Eq. (15) is properly quantized when $k \neq 1$. As for $N_f = 1$ QED$_3$, this can be fixed by declaring that only the monopoles that create multiples of $2k\pi$ flux are allowed in the theory [52,53]: In a bosonic theory (odd $k$), the minimal monopole is a local boson that carries integer Lorentz spin, while in a fermionic theory (even $k$), the minimal monopole is a fermion with half-integer spin. Alternatively, we may introduce an auxiliary Chern-Simons field ($b_\mu$) and rewrite $(1/4k\pi)(a - A) d(a - A)$ as $(1/2\pi) bd(a - A) - (k/4\pi) bbd$ [54]. This is similar to the parton formulation of flux attachment discussed in the previous section. Or finally, we may redefine the gauge charge of the Dirac fermions, $a \rightarrow ka$ [83].

The mass term $m$ is again the tuning parameter for the phase transition. When $m \gg 1$, integrating out the $\psi_i, a$ produces a FCI with $\sigma_{xy} = C_2/(kC_2 + 1)$, while for $m \ll -1$, $\sigma_{xy} = C_1/(kC_1 + 1)$. Tuning $m$ to a critical value ($m_c \sim 0$) results in a critical point between two FCI/FQH phases, which we dub QED$_3$-Chern-Simons theory. When $K = 0$, the critical $m_c$ would be pinned to exactly 0 by the emergent time-reversal symmetry (microscopically, it is an emergent particle-hole symmetry). For $K \neq 0$, the critical mass $m_c$ is finite and will depend on microscopic details.

As we discussed before, a direct transition requires that the other mass terms $\bar{\psi}_i M_{ij} \psi_j (M \neq \text{identity})$ are forbidden by the magnetic translation symmetry arising from the fractional $\phi_{\text{CF}} = p/(C_2 - C_1)$ (with $p$ and $C_2 - C_1$ being coprime). In terms of the electron density $n$ and flux density $\phi$, this constraint becomes

$$n = pC_2/(C_2 - C_1) \mod 1, \quad (16)$$

$$\phi = k \cdot n + \phi_{\text{CF}} = p(kC_2 + 1)/(C_2 - C_1) \mod 1. \quad (17)$$

Thus, to recover, for example, the $\sigma_{xy} = 1/3$ to $2/3$ transition, we set $C_1 = 1$ and $C_2 = -2$, which gives $n = 2p/3$ and $\phi = p$ (modulo integers). This is consistent with the situation described in Sec. III A, where $n = 2/3$ and $\phi = 2$.

The other potentially relevant operator is the monopole operator. Because of the mutual Chern-Simons term $ada$, the monopole operator carries nonzero electrical charge. Therefore, monopole operators are forbidden due to charge conservation, leaving the critical point intact.

B. Pure QED$_3$ theory with $N_f$ flavors

We call theories without a Chern-Simons term for a $(K = 0)$ “pure” QED$_3$. The family of critical theories in Eq. (15) contains pure QED$_3$ with any number $N_f$ of Dirac fermions, with $N_f$ both even and odd.

Pure QED$_3$ with odd-$N_f = 2N + 1$ is realized when $k = 2, C_1 = -N - 1, C_2 = N$. Therefore, it can appear in a system made of fermions, with critical theory.
This describes the transition between the $\sigma_{xy} = N/(2N+1)$ FCI and $\sigma_{xy} = (N+1)/(2N+1)$ FCI, which are the particle-hole symmetric partners in the fermionic Jain sequence. The required CF flux is $\phi_{\text{CF}} = p/(2N+1)$, where $p$ is coprime with $2N+1$. Meanwhile, the fermion density is $n \equiv C_2 \cdot \phi_{\text{CF}} \equiv pN/(2N+1)$ mod 1. Thus, the magnetic flux in the original fermionic system is $\phi = 2 \cdot n + \phi_{\text{CF}} = p$ mod 1, which is an integer.

When $N = 0$, the transition is between a $\sigma_{xy} = 0$ trivial state and a $\sigma_{xy} = 1$ CI. Here, Eq. (18) reduces to the vortex dual of a single free Dirac fermion [51–53]. $N = 1$ gives the $N_f = 3$ QED$_3$ discussed in Sec. III.

Pure QED$_3$ with $N_f$-even is realized when $k = 1$, $C_1 = -N - 1$, $C_2 = N - 1$. Therefore, it can appear in a bosonic system, with critical theory

$$\mathcal{L} = \sum_{i=1}^{2N+1} \bar{\psi}_i (i \partial \phi + \phi) \psi_i - \frac{1}{2} A \partial A + \frac{1}{8 \pi} A A. \quad \text{(18)}$$

This describes the transition between a $\sigma_{xy} = (N-1)/N$ FCI and a $\sigma_{xy} = (N+1)/N$ FCI, which are particle-hole symmetric partners in the bosonic Jain sequence [84,85].

To protect the transition, the CFs must see flux $\phi_{\text{CF}} = p/(2N)$, where $p$ is coprime to $2N$. Meanwhile, the boson density should be $n \equiv C_2 \cdot \phi_{\text{CF}} \equiv p(N-1)/(2N)$ mod 1. Thus, the magnetic flux in the original bosonic system is $\phi = k \cdot n + \phi_{\text{CF}} = 1/2$ mod 1.

When $N = 1$, this theory reduces to the self-dual $N_f = 2$ QED$_3$ that describes the transition between the $\sigma_{xy} = 0$ (Mott insulating phase) and the $\sigma_{xy} = 2$ bosonic integer quantum Hall state [29,30]. This transition can be realized at $\phi = 1/2$ and $n = 1$. Another interesting case is $N = 2$, which describes the transition between $\sigma_{xy} = 1/2$ FCI and the $\sigma_{xy} = 3/2$ FCI. $N_f = 4$ QED$_3$ also arises as the effective theory of a Dirac spin liquid [47,48]. This transition arises at $\phi = 1/2$ and $n = 1/4$. Such a transition may be possible to realize in a cold-atomic system (e.g., bosonic Harper-Hofstadter model [12,86]).

V. PHYSICAL PROPERTIES

A. Critical exponents in large-$N_f$ limit

We now examine some of the physical properties of the resulting critical theory that may be physically measurable. These properties depend on the flavor number of Dirac fermions $N_f$ and the total Chern-Simons coefficient $K$ for $a$.

It is interesting to consider some limits of the critical theory Eq. (15), in which one can hope for some quantitative understanding. One familiar limit is the large-$N_f$ limit, in which $N_f \to \infty$ while the ratio $\lambda \equiv 8K/\pi N_f$ is held fixed. In this limit, one can calculate many critical exponents and transport properties in a controlled manner. Usually large $N_f$ is considered an artificial limit not directly related to any physical system. Here, however, theories with large $N_f$ correspond to a sequence of quantum critical points that in principle can be realized in experiments. This opens the possibility of comparing well-established large-$N_f$ theoretical calculations with future experimental observations.

The scaling dimensions of fermion mass operators, to leading nontrivial order in $1/N_f$, can be calculated for arbitrary $\lambda$ [23,38,39,46,87]. We find that the scaling dimension of the SU($N_f$) adjoint mass operators in Eq. (27), which correspond microscopically to the CDW order parameters with momenta given by Eq. (28), have scaling dimension

$$\Delta_m = 2 - \frac{64}{3\pi^2(1 + \lambda^2)N_f} + O(1/N_f^2). \quad \text{(20)}$$

The SU($N_f$) singlet mass $\sum_i \bar{\psi}_i \psi_i$, which is the operator one tunes across the transition, has dimension

$$\Delta_m = 2 + \frac{128(1 - 2\lambda^2)}{3\pi^2(1 + \lambda^2)^2 N_f} + O(1/N_f^2), \quad \text{(21)}$$

which corresponds to

$$\nu = 1 + \frac{128(1 - 2\lambda^2)}{3\pi^2(1 + \lambda^2)^2 N_f} + O(1/N_f^2). \quad \text{(22)}$$

Some details of the calculation can be found in Appendix A. Notice that at $O(1/N_f)$, for $\lambda < 1$, the adjoint mass is more relevant, while for $\lambda > 1$, the singlet mass becomes more relevant. Of course, translation symmetry prevents the appearance of the adjoint mass terms in the Lagrangian.

The scaling dimension of monopoles has been calculated at the large-$N_f$ limit for both $\lambda = 0$ [36,44] and $\lambda \neq 0$ [88]. In our critical theory, the minimal monopole operator corresponds to the single electron or boson operator. Therefore, their scaling dimension may be detected using STM spectroscopy, as will be discussed in more detail in Sec. V D.

B. Conductivity tensor

We consider the conductivity tensors $\sigma_{ij}$ at the critical points, which are expected to take some universal values. It is easy to calculate $\sigma_{ij}$ if $N_f$ is large, in which case the gauge field fluctuation is suppressed and an RPA-type calculation (familiar in the context of composite fermi liquid [27]) is enough to determine the results to subleading order in $1/N_f$. The electric conductivity tensor is given by
where $\sigma_{\text{Dirac}}$ is the conductivity tensor of the Dirac fermions, and $\hat{\epsilon}$ is the antisymmetric tensor with $\epsilon_{xy} = 1$, and we recall that $K$ is the number of statistical flux quanta attached to the composite fermion. If we neglect gauge fluctuation beyond the RPA order (justified if $N_f$ is sufficiently large), then we can replace $\sigma_{\text{Dirac}}$ by its free-fermion value $\sigma_{\text{FD}}$. The full conductivity (in units of $e^2/h$) tensor will then be

$$\sigma = \frac{1}{k^2} (\sigma_{\text{Dirac}} + K \hat{\epsilon})^{-1} + \frac{1}{k} \hat{\epsilon},$$

(23)

where $\sigma_{\text{FD}}$ is the conductivity tensor of the Dirac fermions, and $\hat{\epsilon}$ is the antisymmetric tensor with $\epsilon_{xy} = 1$, and we recall that $K$ is the number of statistical flux quanta attached to the composite fermion. If we neglect gauge fluctuation beyond the RPA order (justified if $N_f$ is sufficiently large), then we can replace $\sigma_{\text{Dirac}}$ by its free-fermion value $\sigma_{\text{FD}}$. The full conductivity (in units of $e^2/h$) tensor will then be

$$\sigma_{xx} = \frac{1}{k^2} \frac{N_f \sigma_{\text{FD}}}{(N_f \sigma_{\text{FD}})^2 + K^2},$$

$$\sigma_{xy} = \frac{1}{k^2} \frac{K}{(N_f \sigma_{\text{FD}})^2 + K^2}.$$

(24)

The actual value of $\sigma_{\text{FD}}$, in the scaling regime with short-range disorder, is a universal function of the two ratios $\omega/\eta$ and $T/\eta$, where $\eta$ is the effective elastic scattering rate of the Dirac fermions [89]. In the optical limit $\omega \gg T \gg \eta$, $\sigma_{\text{FD}} = \pi/8$. In the DC limit ($\omega = 0$) at low temperature $T \ll \eta$, $\sigma_{\text{FD}} = 1/\pi$. This result, however, should be taken with caution since, at low temperature, disorder may become relevant and eventually drive the critical point away from the clean limit (see, for example, Ref. [90]).

Notice that if $K = 0$, then $\sigma_{xy} = 1/k$ is an exact result due to an emergent particle-hole (or time-reversal) symmetry of the critical theory. Finally, notice that at the free-fermion transition,

$$\sigma = \Delta C \sigma_{\text{FD}} + \tilde{C} \hat{\epsilon},$$

(25)

where $\Delta C$ is the change of total Chern number and $\tilde{C}$ is the average of Chern numbers of the two nearby states.

C. Emergent SU($N_f$) symmetry and charge-density waves

The Lagrangian in Eq. (15) apparently has an emergent SU($N_f$) flavor symmetry that rotates the Dirac fermions:

$$\psi_j \rightarrow U_{ij} \psi_j,$$

(26)

where $U \in \text{SU}(N_f)$. Such a symmetry is absent microscopically—the magnetic translation symmetry acts on the continuum fermion fields as a subgroup of the SU($N_f$) flavor group [Eq. (7)]. Therefore, terms that violate the SU($N_f$) symmetries (but preserve the magnetic translation symmetry) are allowed. Such terms at lowest order contain four-fermion fields. The emergence of the flavor SU($N_f$) symmetry at the fixed point requires the irrelevance of such four-fermion terms, which is true if $N_f$ is sufficiently large [38]. The exact value of a critical $N_f$ (as a function of $K$) is not known. In the following, we will assume that $N_f$ is not too small and the SU($N_f$) symmetry does emerge in the deep infrared, and we obtain consequences of this enlarged symmetry.

Following the spirit of Ref. [38], the emergent SU($N_f$) symmetry relates many operators with very different microscopic origins. The simplest such gauge-invariant operators are the fermion mass bilinears that form an SU($N_f$) adjoint representation:

$$\bar{\psi}_j M_{ij} \psi_j,$$

(27)

where $M$ is an $N_f \times N_f$ invertible traceless Hermitian matrix. There are, in total, $N_f^2 - 1$ independent mass bilinears in the SU($N_f$) adjoint representation. The emergent SU($N_f$) symmetry implies that they all have the same scaling dimensions $\Delta_M$. What do these operators correspond to microscopically? Assuming the CFs transform under translation as in Eq. (7) [81], it is straightforward to see that these operators transform nontrivially under translation symmetry, since the Dirac cones are at different momenta. Notice that, since the mass bilinear operators do not carry a physical electric charge, they do not see any magnetic flux. Thus, they will transform under the usual translation symmetry ($\mathbb{Z} \times \mathbb{Z}$) rather than the magnetic translation symmetry. Following Eq. (7), we find that the bilinears carry lattice momenta

$$(k_x, k_y) = \left( \frac{2\pi n_x}{N_f}, \frac{2\pi n_y}{N_f} \right),$$

$$n_x, n_y \in \{0, 1, \ldots N_f - 1\}, (k_x, k_y) \neq (0, 0),$$

(28)

and there are exactly $N_f^2 - 1$ different momenta of the CDW order parameter, matching the number of independent SU($N_f$) adjoint mass operators. We therefore interpret the SU($N_f$) adjoint mass operators as charge-density wave (CDW) order parameters $\rho_{\kappa}$ at different momenta. Alternatively, notice that the mass operators preserve translations by $N_f$ unit lengths in either the $\hat{x}$ or $\hat{y}$ direction. So these operators transform under the quotient group $(\mathbb{Z} \times \mathbb{Z})/(N_f \mathbb{Z} \times N_f \mathbb{Z}) = \mathbb{Z}_{N_f} \times \mathbb{Z}_{N_f}$, for which there are exactly $N_f^2 - 1$ different nontrivial representations. The mass matrix for the CDW order parameter indexed by $n_x, n_y$ is $M_{ij} = \delta_{i-j, n_x} \exp(i n_y 2\pi l / N)$ in the gauge used in Eq. (7).

In principle, one can turn on an additional symmetry-breaking periodic potential $V_{\kappa}$ at the special momenta of Eq. (28) and measure the resulting response in the CDW order parameter $\rho_{\kappa}$. The emergent SU($N_f$) symmetry implies that, near the critical point, the universal part of the response will be identical for all of the $N_f^2 - 1$ momenta in Eq. (28). More specifically, near the transition we expect a linear response $\rho_{\kappa} = \chi_{\kappa} V_{\kappa}$, where the susceptibility $\chi_{\kappa}$ diverges as $\chi_{\kappa} \sim |m - m_c|^{-\tau_{\kappa}}$ as one approaches the critical
point at $m_c$. From the emergent SU($N_f$) symmetry, the exponents $\gamma = \gamma_{\vec{k}}$ of the special momenta are identical. Exactly at the critical point, we have $\rho_{\vec{k}} \sim (V_{\vec{k}})^{1/\delta_{\vec{k}}}$, where the $\delta = \delta_{\vec{k}}$ of the special momenta are identical. One can also measure the response slightly away from the special momenta: $\vec{k} = (2\pi/N_f)(n_x, n_y) + \Delta \vec{k}$. Then one expects a linear response with $\rho_{\vec{k}} \sim |\Delta \vec{k}|^{2\Delta M - 3}$, again with identical exponents for all $(n_x, n_y)$, where $\Delta M$ is the scaling dimension of the adjoint mass operator. The standard scaling relations among these exponents are $\delta = (3 - \Delta M)/\Delta M$ and $\gamma = \nu(3 - 2\Delta M)$, where $\nu$ is the correlation length exponent. If $\Delta M > 3/2$ (as is the case for large $N_f$), one should include a smooth nonuniversal piece into the susceptibility, which may numerically dominate over the universal singular piece. In this case, the smooth part of the response must be subtracted to probe the universal physics.

1. Numerical evidence for the emergent symmetry

We return to the iDMRG results of Sec. III to look for evidence of an emergent SU($N_f$) symmetry. Since $N_f = 3$, the critical theory will have eight adjoint mass terms that can be probed by the Fourier-transformed electron density $\rho_{\vec{k}}$ for $\vec{k} \in \Lambda$, where $\Lambda = \{(2\pi n_x/3), (2\pi n_y/3)\}$ are the special momenta. To isolate these operators, we suppose the real space density $\rho(r)$ has a decomposition of the form $\rho(r) = \sum_{\vec{k} \in \Lambda} e^{i\vec{k} \cdot \vec{r}} \rho_{\vec{k}}(r) + \cdots$, where the $\rho_{\vec{k}}(r)$ vary slowly over the lattice scale and the neglected terms decay more rapidly. In the 2D limit, the emergent SU(3) symmetry can then be probed by the equal-time correlation function $C_{\vec{k}}(r) = \langle \rho_{-\vec{k}}(r) \rho_{\vec{k}}(0) \rangle$. At the putative critical point, $C_{\vec{k}}$ should show a power-law decay $C_{\vec{k}}(r) \propto r^{-2\Delta k}$. The non-trivial prediction of SU(3) symmetry is that the scaling dimensions $\Delta_{\vec{k}}$ of the eight distinct $\vec{k} \neq 0$ momenta are identical.

However, the interpretation of our numerics is complicated both by the finite circumference of the cylinder and the finite accuracy of the DMRG (as characterized by the bond dimension) [91], introducing a length scale that cuts off the correlations. At long distances along the cylinder, the correlation functions will instead decay exponentially with correlation lengths $\xi_{\vec{k}}$. Luckily, we can also use these correlation lengths to probe the emergent SU(3) symmetry. If the DMRG is sufficiently accurate, the only length scale at the critical point is the circumference of the cylinder $L$, and hence conformal invariance requires $\xi_{\vec{k}} = L/\alpha_{\vec{k}} + \mathcal{O}(L^0)$ for some coefficients $\alpha_{\vec{k}}$. Using the putative conformal invariance (more accurately Lorentz invariance), we can exchange the role of the infinite spatial direction and time ($x \leftrightarrow t$) to reinterpret the equal-time correlation functions of the cylinder as a two-point function in imaginary time, $C_{\vec{k}}(\tau = 0, x, y) = C_{\vec{k}}(x/v, 0, y)$, where $v$ is a velocity. In this alternative view, $v^{\xi_{\vec{k}}^{-1}}$ is the energy of the lowest-energy excited state carrying the corresponding quantum number [92]. If there is an emergent SU(3) symmetry, these states must transform under the adjoint representation of SU(3), and hence, we should find that the “energies” $\xi_{\vec{k}}$ are identical.

One can readily obtain the correlation lengths $\xi_{\vec{k}}$ along the cylinder using the DMRG “transfer matrix technique” [91,93]. Figure 5 shows the dominant correlation lengths $\xi$ of charge-neutral operators that carry the crystal momenta $\vec{k}$. At the critical point, the eight $\vec{k} \neq 0 \in \Lambda$ are found to have nearly the same correlation length. Microscopically, there are two reflection symmetries combined with time reversal, which maps either $k_x \mapsto -k_x$ or $k_y \mapsto k_y$. This reduces the number of independent correlation lengths to three. Moreover, approximate 90° rotation symmetry of the square lattice potential would reduce this further down to two, $(2\pi/3, 0)$ and $(2\pi/3, 2\pi/3)$. Regarding these two points, there is no symmetry reason for $\xi_{\vec{k}}$ to be the same. These eight points have the smallest $\xi_{\vec{k}}^{-1} \sim 0.5$ (largest $\xi$), with the next smallest value $1/\xi \sim 1.1$ located at $\vec{k} = (0, 0)$, which presumably corresponds to the SU(3) singlet mass term. (See vertical plots for distributions of correlation length values in Fig. 5.) We take the near-equality between the eight $\xi_{\vec{k} \neq 0}$, which are nevertheless distinct from $\xi_{\vec{k} = 0}$, as evidence for the emergence of SU(3) symmetry. Moreover, the large-$N_f$ calculation of the scaling dimensions in Eqs. (20) and (21) agrees with our observation that the SU(3) singlet mass term decays faster (smaller $\xi$) than the SU(3) adjoint mass terms as $\Delta_m > \Delta_M$. Once we tune away from the critical point (Fig. 5), the correlation length becomes smaller and there is no emergent SU(3) symmetry.

D. Magnetic monopoles

In compact QED$_3$, magnetic monopoles that insert $2\pi$ units of flux of the emergent gauge field represent a fundamental class of local operators which, unlike other gauge invariant operators such as fermion bilinears, cannot be written as polynomials of the fields. Nevertheless, they correspond to local operators. While we have previously shown that fermion bilinears $\bar{\psi}M\psi$ correspond to CDW order at different wave vectors, in this section we identify the physical operators corresponding to magnetic monopoles. In fact, for the theory that describes the $\sigma_{xy} = 1/3$ to $\sigma_{xy} = 2/3$ transition, we argue that they correspond to the electron creation/destruction operator, which can be measured by experimental probes like scanning tunneling microscopy (STM).

Consider a general strength-$q$ monopole that creates $2\pi q$ flux of the U(1) gauge field $a_{\mu}$, in a theory with $N_f$ massless Dirac fermions and Chern-Simons level $K$. 031015-10
To avoid the parity anomaly in conventional QED$_3$-Chern-Simons theories, $N_f/2 + K$ must be an integer [36]. However, as discussed at the end of Sec. III C, we will discuss seemingly anomalous theories where $N_f/2 + K = 1/k$, mod 1, which are consistent as long as the allowed monopoles have strength in multiples of $k$. A particularly simple picture of monopole operators arises in the large-$N_f$ limit in the radial quantization picture, where one considers Dirac fermions on the surface of a sphere pierced by $2\pi q$ units of magnetic flux [36,44,88]. The magnetic flux gives rise to $q$ zero modes for each fermion species. If $K = 0$, gauge invariance demands that we fill half of these zero modes. Below, we will specialize to the case of the $\sigma_{xy} = 1/3$ to $\sigma_{xy} = 2/3$ transition, for which $N_f = 3$, $K = 0$, and the allowed monopoles have strengths that are multiples of $k = 2$. The generalization to other transitions will be discussed elsewhere.

First, let us determine the spin, statistics, and global symmetries transformation properties of the monopole operators with strength $k = 2$. Note that this leads to two zero modes (labeled $m = \pm 1$), which transform as spinors under rotation, for each of the $N_f$ flavors ($a = 1, 2, 3$). Filling half of these six zero modes implies that there are $6 C_3 = 20$ monopole operators, which can be written as $\psi_{m_1 a_1} \psi_{m_2 a_2} \psi_{m_3 a_3} |\text{vac}\rangle$. Importantly, these are fermionic operators as can be seen from their half integer spin, and as discussed in Refs. [52,53]. Furthermore, they carry unit charge under the global $U(1)$, as can be seen from the mutual Chern-Simons term in Eq. (11). Clearly, the only physical local operator that is a charged fermion is the electron. Finally, let us discuss the transformation of the monopoles under the $SU(N_f = 3)$ flavor symmetry and Lorentz spin of the 20 strength-2 monopoles, which are determined from the pattern of filling of the zero modes. After some algebra, the monopoles can be grouped into two categories: (i) adjoint of $SU(3)$, Lorentz spin $S = 1/2$, and (ii) singlet of $SU(3)$, Lorentz spin $S = 3/2$.

As a consistency check, note that the $SU(3)$ adjoint rep has dimension $D = 8$, and the singlet of $SU(3)$ has dimension $D = 1$. Combining this with the $2S + 1$ spin degeneracies, we recover $2 \times 8 + 4 = 20$ monopoles in total. In the large-$N_f$ limit [36,44], the strength-2 monopole has scaling dimension 0.673$N_f$. By naively taking $N_f = 3$, we get a scaling dimension $\Delta \approx 2.019$. The degeneracy between the 16 adjoint and the 4 singlet monopoles will split with higher order correction included. (We note that the $1/N_f$ correction obtained in Ref. [44] may not apply here.)

The existence of $16 + 4$ electronlike monopole operators has some interesting experimental consequences, so we analyze their relation to the electron in further detail. The local electron operator $c$ should have overlap with all symmetry-allowed local operators of the CFT, leading to a decomposition of the general form

\begin{equation}
\end{equation}
\[ c(x) = \sum_{\alpha} u_{\alpha}(x) e^{ik_{\alpha}x} M_{\alpha}(x) + \cdots \]  

Here \( M_{\alpha}(x) \) runs over the 20 4\( \pi \)-monopoles, \( u_{\alpha}(x) \) is a periodic function within the unit cell, and \( k_{\alpha} \) is the lattice momentum of monopole \( \alpha \). The lattice symmetries, specifically the magnetic algebra and a possible \( C_n \) symmetry, will place some interesting constraints on the \( u_{\alpha} \) and \( k_{\alpha} \). To find these constraints, we must work out how the lattice symmetries act on the monopoles. The microscopic lattice symmetries will act as a subgroup of the larger emergent \([\text{Lorentz} \times \text{SU}(3) \times \text{U}(1)_{\text{flux}}]\) symmetry. Specifically, under a lattice symmetry \( R \), a monopole will transform under the general form

\[
R: M_{S,m,a}^\dagger \rightarrow L_{S,m}(R) U_{a,b}(R) e^{i\theta(R)} M_{S,m,b}^\dagger.
\]  

The monopoles are labeled by their IR quantum numbers, namely, Lorentz spin \( S \); the spin index \( m = -S, -S+1, \ldots, S \); and SU(3) flavor indices \( a, b \). The first term \( L_{S,m}(R) \) represents the Lorentz transformation, which may depend on the Lorentz spin and spin index. The second term \( U_{a,b}(R) \) represents the SU(3) transformation. The last term \( e^{i\theta(R)} \) represents the \( U(1)_{\text{flux}} \) transformation, which comes from a Dirac sea contribution [48,94,95]. Therefore, it is independent of the Lorentz spin and SU(3) index.

We will consider the lattice translations along two primitive directions of a lattice \( (T_1 \text{ and } T_2) \), as well as the lattice rotation \( C_n \). We assume they embed into the Lorentz part as the usual Euclidean space group,

\[
L_{S,m}(T_i) = 1, \quad L_{S,m}(C_n) = e^{i2\pi m/n}.
\]  

For the SU(3) flavor rotation, since we only have SU(3) singlet and adjoint monopoles, they are in the same SU(3)-reps as the bilinear masses discussed in Sec. V C. Specifically, we have \( U = 1 \) for the SU(3) singlet monopole, and for the SU(3) adjoint monopole we have

\[
U_{a,b}(T_1) = \delta_{a,b} e^{ik_{1,a}}, \quad U_{a,b}(T_2) = \delta_{a,b} e^{ik_{2,a}},
\]  

where the eight members of the adjoint representation are labeled by the “momenta” \((k_{1,1}, k_{2,1}, (2\pi n_1/3), (2\pi n_2/3))\) with \((n_1, n_2) \neq 0 \) and \( a = 1, 2, \ldots, 8 \). The \( C_n \) must act on these just like they would on momenta in the Brillouin zone. Specifically, for \( C_4 \) (square lattice) or \( C_6 \) (triangular lattice), and an appropriate ordering of \( a = 1, \ldots, 8 \),

\[
U(C_4) = \begin{pmatrix}
0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 1
\end{pmatrix},
\]

and

\[
U(C_6) = \begin{pmatrix}
0 & 1 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 1 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 1 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 1 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 1 & 0 & 0 \\
1 & 0 & 0 & 0 & 0 & 0 & 0 & 0 \\
0 & 0 & 0 & 0 & 0 & 0 & 0 & 1 \\
0 & 0 & 0 & 0 & 0 & 0 & 1 & 0
\end{pmatrix}.
\]

At last, we need to work out the phase factor \( \theta(R) \) from the \( U(1)_{\text{flux}} \) rotation. Physically, it comes from the contribution of Dirac sea, which can be determined numerically (e.g., see Refs. [94,95]). Usually, \( \theta(R) \) can only take quantized values due to the symmetry constraint. Specifically, on the square lattice, we have

\[
T_2 C_4 = C_4 T_1, \quad T_1 C_4 = C_4 T_2^{-1}, \quad (C_4)^4 = 1.
\]  

On the triangular lattice, we have

\[
C_6 T_2 = T_1^{-1} C_6, \quad T_2 C_6 = C_6 T_1 T_2, \quad (C_6)^6 = 1.
\]  

The monopoles are local electron operators seeing an integral flux, so they should satisfy the above algebraic relations. Based on the transformation of the SU(3) singlet monopole, we will have

\[
\theta(T_i) = s\pi, \quad \theta(C_4) = \frac{(2n + 1)\pi}{4}
\]  

on the square lattice. Here, \( s \) and \( n \) are integers that can be determined numerically. Similarly, on the triangular lattice, we have
\[ \theta(T_i) = 0, \quad \theta(C_6) = \frac{(2n + 1)\pi}{6}. \]  

1. Experimental consequences

With the symmetry properties of the monopoles in hand, we are ready to discuss their experimental detection. Since the electron can be expanded in monopole operators [see Eq. (29)], any measurement sensitive to the electron Green’s function will probe the two-point function of the monopoles. For energy resolved spectroscopies, such as STM and ARPES, each monopole will contribute an energy dependence of the form \[ E^{2\Delta_\alpha - 1} \], where \[ \Delta_\alpha \] is its scaling dimension. In our case, there are two such dimensions, corresponding to SU(3) singlet and adjoint monopoles, which may be quantitatively similar. So it would be particularly spectacular if symmetry could be used to impose selection rules whereby the two dimensions can be measured separately.

We first consider a momentum resolved spectroscopy such as ARPES (or more heterostructures, planar tunneling [96]), which probes the spectral function \[ A(E, k) \]. Following Eq. (29), \[ A(E, k) \] will contain a singular component from each monopole with momentum \[ k = k_\alpha \], which is just the action of \( T_{1/2} \) on the monopole. On the triangular lattice, the low-energy spectral weight will peak at \[ (k_1, k_2) = \{(2\pi n_1/3), (2\pi n_2/3)\} \] for \( n_1, n_2 \) = (0, 0) corresponds to the \( S = 3/2 \), SU(3) singlet monopoles, while the other eight momenta correspond to the \( S = 1/2 \), SU(3) adjoint monopoles. So momentum perfectly unravels the two exponents: \[ A(E, k = 0) \propto E^{2\Delta_{s-1/2-1}}, \] while \[ A(E, k_\alpha \neq 0) \propto E^{2\Delta_{s-1/2-1}}. \] On the square lattice, the results are similar except that the relevant momenta may have a shift of \( (\pi, \pi) \) coming from the contribution \( \theta(T_i) = \pi \) in Eq. (41). The eight distinct momenta should again be degenerate, giving another way to detect the emergent SU(3) symmetries.

The second option is to use STM spectroscopy. At a generic point, the STM will couple to both types of monopoles, so that \[ (dI/dV) \sim AV^{2\Delta_{s-1/2-1}} + bV^{2\Delta_{s-1/2-1}} + \ldots \] However, if the STM is above a point-group symmetry (a “Wyckoff position”), then the STM will only measure monopoles with zero lattice angular momentum about the point [these extinctions arise from the constraints \( C_\alpha \) imposes on the \( u_\alpha(x) \) of Eq. (29)]. Combining the results of \( L_{S,m}(C_\alpha), U(C_\alpha), \) and \( \theta(C_\alpha) \), we find that the 16 SU(3) adjoint monopoles \( S = 1/2 \) will always contain both zero and finite angular momentum monopoles, regardless of whether we consider the triangular or square lattice, so their scaling dimension will always manifest in \( dI/dV \). The four SU(3) singlet monopoles \( S = 3/2 \), on the other hand, may or may not contain zero angular momentum monopoles—specifically, they will not on the triangular lattice if \( n = 2, 3 \) in Eq. (42). This case would be particularly convenient, as the \( \Delta_{3/2} \) contribution to \( dI/dV \) would vanish above these high-symmetry points.

In the presence of dilute impurities, STM can also be used to analyze the wave vectors present in the resulting Friedel oscillations. Analyzing this “quasiparticle inference” [97] would be another way to obtain a \( k \)-resolved monopole spectroscopy.

VI. CONFINEMENT TRANSITION OF THE 1/2 LAUGHLIN STATE: APPLICATION OF LEVEL-RANK DUALITY

Some of the critical theories in Eq. (15) may enjoy a further enhanced symmetry. One example is the phase transition between the bosonic \( \nu = 1/2 \) Laughlin state and a trivial insulating phase. This transition can be described by QED\(_3\)-Chern-Simons theory with \( C_1 = 0, C_2 = 1, \) and \( k = 1 \) [23,28],

\[ \mathcal{L} = \bar{\psi}(i\partial + \phi)\psi + \frac{3}{8\pi} ada - \frac{1}{2\pi} Ada + \frac{1}{4\pi} AdA - m\bar{\psi}\psi. \]  

The critical theory has a bosonic dual [54,55], which is [22]

\[ \mathcal{L} = |(\partial \phi - ib)\phi|^2 - \frac{2}{4\pi} bdb + \frac{1}{2\pi} Adb - m|\phi|^2 - u|\phi|^4. \]  

Here, \( \phi \) is an O(2) scalar, and \( b \) is a U(1) dynamical gauge field. Since \( \phi \) itself carries a unit charge of the gauge field \( b \), \( \phi \) can be understood as the semionic quasiparticle of the 1/2 Laughlin state. Tuning the mass term \( m|\phi|^2 \) gives two phases and transition: (i) For the positive mass, the semions are gapped and we get the 1/2 Laughlin state. (ii) For the negative mass, the \( \phi \) are condensed and the gauge field \( b \) is Higgsed, giving rise to a trivial insulating state.

At face value, the above two critical theories only have a U(1) symmetry, the flux conservation of the dynamical gauge field (microscopically, the number conservation of bosons). However, it was conjectured that they may have an enlarged SO(3) symmetry [69]. It is based on the conjectured level-rank duality [68], namely, those two theories may be dual to a SU(2) Chern-Simons theory,

\[ \mathcal{L} = \bar{\Psi}(i\partial + A/2)\Psi + \frac{1}{8\pi} (\text{CS}[\alpha]) + \frac{1}{16\pi} AdA - m\bar{\Psi}\Psi. \]  

Here, we have a SU(2) fundamental Dirac fermion \( \Psi \) coupled to a level-1/2 SU(2) Chern-Simons gauge field \( \alpha_\mu \). \( A_\mu \) is a U(1) probing field. \( \text{CS}[\alpha] \) is a shorthand for \[ c_{\mu \nu \lambda}[\alpha_\mu, \partial_\nu \alpha_\lambda + \frac{i}{2} \alpha_\rho \alpha_\lambda \alpha_\rho], \] which is \( 4\pi \) times the SU(2) Chern-Simons term of \( \alpha_\mu \) with level 1. By tuning the mass of Dirac fermions, one would either get a SU(2), Chern-Simons theory or zero Chern-Simons: the former...
corresponds to the $1/2$ Laughlin state [98], while the latter corresponds to a trivial insulating phase.

All three theories can describe the transition from the $1/2$ Laughlin state to a trivial insulator. Therefore, one would conjecture that they are dual to each other. Furthermore, one would expect the first two theories to have an enhanced symmetry [rather than a naive U(1) symmetry], since the last one has a manifest SO(3) symmetry—the Dirac fermion $\Psi$ forms a fundamental representation of both the SU(2) gauge symmetry and the SO(3) global symmetry. This duality and symmetry enhancement were already conjectured in Ref. [69], and here, we take one step further to identify the relation among operators in three different theories,

\[ \psi_\mu \sim |\phi|^2 \sim \bar{\Psi} \Psi, \] (46)

\[ \nabla \times a \sim \nabla \times b \sim \bar{\Psi} \sigma_\mu \Psi, \] (47)

\[ M_a \psi^\dagger \sim M_b (\phi^\prime)^2 \sim \Psi^T (\sigma_\mu \sigma_\nu \otimes \tau_y) \Psi. \] (48)

The $M_a$ ($M_b$) is the bare monopole that creates the $2\pi$ flux of the gauge field $a_\mu$ ($b_\mu$). Because of the Chern-Simons term, one should attach $\psi_\mu^\dagger (|\phi^\prime|^2)$ to the monopole in order to have a local (gauge neutral) object (for instance, see Ref. [88]). $\sigma_{\mu=1,2,3}$ are Pauli matrices acting on the Dirac index, while $\tau_y$ acts on the gauge index.

The first line [Eq. (46)] is the mass term that tunes through the phase transition and is a scalar under the SO(3) (and Lorentz) symmetry. The second line identifies the flux in the U(1) gauge theory with the gauge-invariant density and current of $\Psi$ fermions in the SU(2) gauge theory. In the third line, we have the monopole operators in the U(1) gauge theory dual to the pairing amplitude and current of $\Psi$ fermions in the SU(2) gauge theory. To understand the last equation, we should realize that because of the Chern-Simons term, the monopole operators are carrying Lorentz spin 1 (hence, they have three complex components). Moreover, $[\nabla \times a, \text{Re}(M_a \psi^\dagger), \text{Im}(M_a \psi^\dagger)]$ forms a SO(3) vector, and they are the conserved current of the conformal field theory, whose scaling dimension is precisely 2.

We expect that the operators in Eqs. (46)–(48) are the ones with lowest scaling dimension. Therefore, they will give the dominant contribution to the physical operator correlation functions. Since the boson creation (or density) operator has the same global quantum number as the monopole (or flux) operator, we will have

\[ b_0^\dagger b_\rho \sim 1/r^4, \quad n_0 n_\rho \sim 1/r^4. \] (49)

Therefore, in a bosonic system with only particle conservation, the critical point would enjoy an enlarged SO(3) symmetry that makes the boson creation operator degenerate with the boson density operator. The above results may be tested in numerical simulations or experiments. We remark that the SO(3) symmetry is most transparent in the chiral spin liquid system [99–103], where it is nothing but the spin rotation symmetry. [The SU(2) gauge theory can be constructed from a SU(2) parton construction [98].] In this context, the spin operator $\vec{S}$ has scaling dimension 2, while the dimer operator $\vec{S}_0 \cdot \vec{S}_1$ corresponds to the mass term in Eq. (46).

VII. EXPERIMENTAL REALIZATION

In this section, we briefly describe the experimental setup for FCI transitions, and the scenario we believe is simplest to realize. The required ingredients are Landau levels and a tunable periodic potential, which are already available in experiments. There is no particular type of tunability required, e.g., one could change the detailed form of the superlattice $V_m$, the Landau level spacing, or various pseudospin Zeeman fields, but conceptually it is simplest to tune the overall strength of the potential ($U_0$ in our model). Then, (i) for small potential strength, the system realizes a conventional FQH state that has electrons partially filling the lowest Landau level and (ii) for large potential strength, the Landau level splits into subbands, and the electrons may partially fill a subband, yielding a FCI state. A phase transition between the FQH and the FCI could then be expected at a critical potential strength, as found in our numerics. An experimental setup with a tunable potential strength has been realized recently in Refs. [7,64], where a range of $U_0/E_c$ can be realized.

The existence of a transition can be diagnosed from the behavior of the gap in a Wannier plot, as in Fig. 1. If two experimentally observed $(C,s)$ trajectories intersect at $n_s$, $\phi_s$, one or both with fractional $C$, and the pair exchange stability as the potential strength is tuned, then QED$_3$ may describe the transition. To fall within our QED$_3$-Chern-Simons analysis, the two gaps should be attributable to states in the same Jain sequence (e.g., the same $k$), and for pure QED$_3$, the two states should be particle-hole conjugates \[ [\sigma_{xy} = p/(2p+1) - \sigma_{xy} = (p+1)/(2p+1)]. \] We describe the $n_s$, $\phi_s$ where they might appear in Appendix B 2.

While the numerical results we have presented thus far were for a FQH-FCI transition, experimentally a FQH-ICI (integer Chern insulator) transition may be a simpler initial target, since ICI states are more stable and easy to realize in experiment. For example, consider a transition between $\sigma_{xy} = 1/3$ FQH and $\sigma_{xy} = 1$ ICI, which can occur at flux density $\phi_s = 3/2$ and electron density $n_s = 1/2$, with the same potential as in the FQH-FCI transition of Sec. III. For small $U_0$, the $\sigma_{xy} = 1/3$ FQH state is realized. For large $U_0$, the LLL splits into three subbands, and the electrons completely fill the lowest subband whose Chern number is 1. So $U_0/E_C$ is expected to tune between the two, realizing $N_f = 2$, $K = 1/2$ QED$_3$-Chern-Simons described further in Appendix B 1. We have also carried out iDMRG
Phase transition from $\sigma_{xy} = 1/3$ to $\sigma_{xy} = 1$

FIG. 6. DMRG simulation result on infinite cylinder geometry with circumference size $L_y = 24.6l_B$. $\phi = 3/2$, $n = 1/2$, $V_1 = V_2 = 1$, $V_3 = V_4 = 1.6$, while changing the potential strength $U_0$. The blue line represents the change of Hall conductivity, which is measured at bond dimension $\chi = 2000$. Red lines represent the change of correlation length with bond dimension $\chi$. As in the case of the transition between $\sigma_{xy} = 1/3$ FQH and $\sigma_{xy} = 2/3$ FCI, numerical evidence supports a continuous transition.

VIII. SUMMARY AND DISCUSSION

Motivated by the recent experimental realization of FCIs in graphene heterostructures, we have shown how phase transitions between different FCIs induced by changing the lattice potential can be used to realize the whole family of QED$_3$-Chern-Simons theories. A key ingredient is that the magnetic algebra of the microscopic model can be used to realize multiple symmetry related Dirac fermion flavors ($N_f > 1$) without further fine-tuning. At the critical point, this leads to an emergent SU($N_f$) symmetry that can be diagnosed from the electron compressibility at finite momentum.

We hope our work will stimulate further investigation of QED$_3$-Chern-Simons theory. For example, previous literature has mostly focused on the situation where $N_f/2 + K$ is an integer due to the parity anomaly [36,88]. Nevertheless, it has now been realized that this constraint can be relaxed: $N_f/2 + K$ can be a half integer, or other fractions. Mathematically, the parity anomaly can be avoided by either forbidding certain monopole operators [52,53], by introducing an auxiliary topological Chern-Simons term [54], or redefining the gauge charge of Dirac fermions [83]. These new sequences of “pseudoanomalous” QED$_3$-Chern-Simons theory have rarely been investigated [83]. The critical theories, which are straightforward within the proposed experimental realization, have $N_f/2 + K$ half integer. For example, the transition we studied in Sec. III (between the $\sigma_{xy} = 1/3$ state and $\sigma_{xy} = 2/3$ state) has $N_f = 3$ and $K = 0$. It will be interesting to have a better theoretical understanding of these theories.

Another interesting direction is to understand the properties of monopoles in QED$_3$-Chern-Simons theory [36,44,45,88]. As discussed, the monopole is nothing but the electron, so the scaling dimensions of the monopoles can be detected using standard spectroscopic techniques such as STM. On the other hand, there are also opportunities to explore these critical theories under the deformation of adding monopole terms. For a given $N_f$, $K$ QED$_3$-Chern-Simons theory, if the monopole operators proliferate (condense), will the theory flow to a symmetry breaking state, a topologically ordered state, or a new CFT [58]? In the context of the FCI transition, monopole proliferation may be achieved by proximity to a superfluid or superconductor.

In the current work, we have not addressed the effect of the long-range Coulomb interaction and disorder. In graphene heterostructures, the long-range Coulomb tail is screened by the proximity to metallic gates, so it can likely be ignored. Disorder, however, will be present. While the underlying graphene, as well as moiré superlattices, are extremely pristine, the most tunable superlattice architecture, gate-patterning [7], will likely prove much dirtier. However, in contrast to the conventional quantum plateau transition, here it is the lattice potential rather than disorder that enables a direct transition between different plateaus. Therefore, the disorder may be ignored when the temperature is larger than the effective scattering rate. Nevertheless, it is physically interesting to consider the effect of Coulomb interactions and/or disorder. These perturbations may be marginal in the UV and become either marginally relevant or irrelevant in the deep IR. Since the perturbations are relevant, the critical theory will lose conformal invariance and flow into another fixed point. The new fixed point could either correspond to a gapped state or a metallic state. The answer to these questions will depend on the details (i.e., $N_f$ and $K$), and our understanding is incomplete even in the large-$N_f$ limit [24,90,104]. These questions are left for future work.

ACKNOWLEDGMENTS

APPENDIX A: DETAILS OF THE LARGE-$N_f$ CALCULATION

The calculation will largely follow Refs. [38,39]. The only modification is on the photon propagator due to the Chern-Simons term.

We assume large $N_f$ and $k$, with the ratio $\lambda = (8k/\pi N_f)$ fixed. The effective Euclidean Lagrangian of the gauge field $a_\mu$, at leading order in $1/N_f$, is given by

$$L[a_\mu] = \frac{N_f}{16}|q||\vec{a}(q)|^2 + \frac{k}{4\pi} \epsilon_{\rho\mu\nu} q_\rho a_\mu(q) a_\nu(-q) + \frac{N_f}{8|q|}(\vec{q} \cdot \vec{a})^2,$$

where the first term comes from the one-loop contribution from the Dirac fermions, the second term is the Chern-Simons term, and the last term is a (nonlocal) gauge-fixing term. The original Maxwell term is irrelevant and omitted.

We can now choose a convenient $\xi$ (Feynman gauge) to make the photon propagator of the following form:

$$\Sigma_1(k) = \frac{24}{\pi^2 N_f (1 + \lambda^2)} (im) \ln(|k|/\Lambda),$$

and

$$\Sigma_2(k) = \frac{64(1-\lambda^2)}{\pi^2 N_f (1 + \lambda^2)^2} (im) \ln(|k|/\Lambda).$$

The scaling dimension $\Delta_{m_s}$ can then be extracted following the standard procedure:

$$\Delta_{m_s} = 2 - \frac{64}{3\pi^2(1+\lambda^2)N_f} + \frac{64(1-\lambda^2)}{\pi^2(1+\lambda^2)^2N_f} + O(1/N_f^2).$$

The microscopic setting for the transition

In this section, we will describe the microscopic setting for the phase transition. The results are summarized in Table I.

1. FQH-ICI transition

Compared with the FCI, ICI is much easier and robust to realize in experiments. Therefore, it is interesting to consider the transition from the $\nu = p/(2p + 1)$ FQH
phase to a ICI phase. Since the ICI phases with \( C = 0, 1 \) also belong to the Jain sequence, they correspond to composite fermions from the \( C_l = 0 \) or \( C_l = -1 \) integer state, so the FQH-ICI transition can be described by our QED\(_3\)-Chern-Simons theory [Eq. (15)]. Specifically, the transition to the \( C = 0 \) ICI has the critical theory,

\[
\mathcal{L} = \sum_{i=1}^{p} \bar{\psi}_i (\partial \psi_i - i \phi) + \frac{p + 1}{8 \pi} \alpha \alpha - \frac{1}{4 \pi} \alpha A.
\]

(B1)

Similarly, the transition to the \( C = 1 \) ICI is described by

\[
\mathcal{L} = \sum_{i=1}^{p+1} \bar{\psi}_i (\partial \psi_i - i \phi) + \frac{p + 1}{8 \pi} \alpha \alpha - \frac{1}{4 \pi} \alpha A.
\]

(B2)

We do not write the mass term \( m \sum \bar{\psi} \psi \) explicitly, but we remark that because of the finite Chern-Simons term, the mass \( m \) should be tuned in order to hit the criticality.

Microscopically, the FQH-ICI transition is indeed straightforward to realize. Again, we consider the Landau levels under a weak superlattice potential. For example, suppose we have a superlattice with the flux density \( \phi = (2p + 1)/p \) and particle density \( n = 1 \) in each unit cell. When the potential is weak, the \( \nu = p/(2p + 1) \) FQH is naturally realized. When the potential is strong compared with the Coulomb energy, the LLL splits into \( 2p + 1 \) subbands, and the \( p \) lowest subbands are filled. By a proper choice of potential pattern, it is not hard to realize that the \( p \) lowest subbands have the total Chern number \( C = 0 \). Consequently, we could imagine a transition from the \( \nu = p/(2p + 1) \) FQH to the \( C = 0 \) ICI by tuning the potential strength. Furthermore, the composite fermion sees an effective flux \( \phi_{CF} = 1/p \), which means that the magnetic translation symmetry will protect \( p \) Dirac cones at the critical point.

Similarly, we can construct the model for the transition between the \( \nu = p/(2p + 1) \) FQH and the \( C = 1 \) ICI state. One way to realize it is to have the flux \( \phi = (2p + 1)/(p + 1) \) and density \( n = p/(p + 1) \) in each unit cell. In the weak potential limit, we have the \( \nu = p/(2p + 1) \) FQH state. In the strong potential limit, the Landau level splits into \( 2p + 1 \) subbands, and the \( p \) lowest subbands are filled. The total Chern number of the lowest \( p \) subbands can be \( 1 \) under a proper choice of potential pattern. Also, it is easy to show that the \( p + 1 \) Dirac cones at the critical point are protected by the magnetic translation symmetry since the effective flux of the composite fermion is \( \phi_{CF} = 1/(p + 1) \).

Indeed, a simple square lattice potential in Eq. (8) gives precisely the required free-fermion band structure, namely, the lowest \( p \) subbands have a total Chern number \( 0 \) \([\phi = (2p + 1)/p]\) or \( 1 \) \([\phi = (2p + 1)/(p + 1)]\).

### 2. Odd flavor QED\(_3\) transition

The pure QED\(_3\) theory describes the transition between the particle-hole conjugate partner of the Jain sequence states. For the fermionic system, the pure QED\(_3\) theory [Eq. (18)] has the odd number \((2p + 1)\) of Dirac fermions, and the transition happens between the \( \sigma_{xy} = p/(2p + 1) \) and \( \sigma_{xy} = (p + 1)/(2p + 1) \) states. As we already discussed in Sec. III, the \( 1/3 \) to \( 2/3 \) (i.e., \( p = 1 \)) transition can be realized in a simple setting. Here, we generalize this setting to the arbitrary \( p \).

We consider a superlattice potential that has the flux \( \phi = 2p \) and the density \( n = 2p^2/(2p + 1) \) in each unit cell. The filling factor is \( \nu = n/\phi = p/(2p + 1) \); thus, a FQH state is naturally expected when the potential is weak. Once the potential is finite, the lowest Landau level splits into \( 2p \) bands. Under a square lattice potential [e.g., Eq. (8) with \( V_1 = V_2 = 1, 1 \gg V_3 = V_4 > 0 \)], the Chern number of the bands is \( C_l = 0 \) when \( l = 1, \ldots, p - 1, p + 1, \ldots 2p \), and \( C_p = 1 \). The electrons completely fill the \( p - 1 \) lowest bands \((C = 0)\) and partially fill [with the filling factor \( (p + 1)/(2p + 1) \)] the \( C = 1 \) band (the \( p \)th band). Hence, the \( \sigma_{xy} = (p + 1)/(2p + 1) \) FCI may appear, and the \( p/(2p + 1) - (p + 1)/(2p + 1) \) transition could be realized by tuning the potential strength. Furthermore, one can show that the composite fermion has an effective flux \( \phi_{CF} = \phi - 2n = 2p/(2p + 1) \); hence, the \( 2p + 1 \) Dirac cones of the critical theory are protected by the magnetic translation symmetry.

To realize the above scenario microscopically, one may need to further adjust the potential pattern as well as the interaction. If the lattice potential is not adjusted appropriately, we may fall into a Fermi liquid phase or a CDW phase, since these two phases can possibly compete with a FCI phase when the potential is nonzero. As we discussed in Sec. III, for the case with \( p = 1 \), one needs to adjust the diagonal potential \( V_3 = V_4 \) \((\approx 1.4V_1)\) to have a large flatness ratio in the \( C = 1 \) band. The gapped \( \sigma_{xy} = 2/3 \) phase is only observed for the small range of \( V_3/V_1 \) near...
1.4 and, outside of this range, a metallic phase was observed, signaling the metal-FCI transition. We expect that similar tuning of the lattice potential would also be required for a larger \( p \), whose systematic investigation is left for future work.

**APPENDIX C: MISCELLANEOUS IN NUMERICS**

When we perform the DMRG simulation for a lattice model with an emergent gauge field and Dirac fermions, we should be careful about a flux trapped along the cylinder. In such a situation, gaplessness of the Dirac fermions would be modified because the trapped flux would change the boundary condition for Dirac fermions along the finite circumference [50]. Thus, to properly investigate the critical dynamics in a cylinder, we need to address the question of whether there exists a trapped flux through the cylinder, and what the momenta of the Dirac points are. In the case of a fractional quantum Hall problem, the trapped flux is associated with a total momentum of the topological sector of the system [77,105]. For the \( \sigma_y = 1/3 \) to \( \sigma_y = 2/3 \) transition that we considered in the main text, the Dirac fermions are hitting gapless momenta points if there is no gauge flux trapped, which corresponds to \( K_{tot} = 0 \). The effective gauge flux of Dirac fermions can also be tuned by inserting the flux by hand [50]. Figure 7 shows how the system responds under the flux insertion starting from the \( K_{tot} = 0 \) topological sector. One can see that the correlation length and energy are peaked at the zero flux insertion, which agrees with our theoretical expectation.

**FIG. 7.** The response of the \( \sigma_y = 1/3 \) to \( \sigma_y = 2/3 \) transition under the adiabatic flux insertion from 0 to \( 6\pi \). Through this procedure, we can also calculate the Hall conductance by measuring the charge transported through the flux insertion, where we changed the flux by \( 2\pi/10 \) in each step. Here, the potential strength \( U_0 = 0.6 \) and the bond dimension \( \chi = 2000 \). Both the energy and correlation length change as a function of \( \Phi \) with a periodicity of \( 6\pi \), three flux quanta. Peak structures in both plots reveal the existence of the emergent Dirac fermions in the low-energy effective theory.

[81] Strictly speaking, each symmetry operation on the CFs is ambiguous up to an overall phase, because they couple to a U(1) gauge field, but this ambiguity cancels for the bilinears.
[92] On the equality $\xi^2 = \frac{1}{k}$, the scaling dimension of the most relevant primary operator carrying quantum number $\kappa$ up to a normalization factor. But here we are simulating a cylinder/torus geometry instead of the sphere, so there is no precise correspondence of this form. Nevertheless, the equality of the $\xi$ will follow from the emergent SU($N_f$).
